1 ABSTRACT

2 Milk provides energy and nutrients considered protective for bone. Meta-analyses of cohort studies

- 3 have found no clear association between milk drinking and risk of hip fracture, and results of recent
- 4 studies are contradictory. We studied the association between milk drinking and hip fracture in
- 5 Norway, which has a population characterised by high fracture incidence and a high calcium intake.
- 6 Baseline data from two population-based cohorts were used: The third wave of the Norwegian
- 7 Counties Study (1985-88) and the Five Counties Study (2000-2002). Diet and lifestyle variables
- 8 were self-reported through questionnaires. Height and weight were measured. Hip fractures were
- 9 identified by linkage to hospital data with follow-up through 2013. Of 35,114 participants in the
- 10 Norwegian Counties Study, 1,865 suffered a hip fracture during 613,018 person-years of follow-up.
- 11 In multivariable Cox regression, hazard ratios (HR) per daily glass of milk were 0.97 (95%
- 12 confidence interval (CI) 0.92, 1.03) in men and 1.02 (95% CI 0.96 to 1.07) in women. Of 23,259
- 13 participants in the Five Counties Study, 1,466 suffered a hip fracture during 252,996 person-years
- 14 of follow-up. HR for hip fractures per daily glass of milk in multivariable Cox regression were 0.99
- 15 (95% CI 0.92, 1.07) in men and 1.02 (95% CI 0.97, 1.08) in women. In conclusion, there was no
- 16 overall association between milk intake and risk of hip fracture in Norwegian men and women.

Leep'eon

17 INTRODUCTION

18 Hip fractures are a serious public health problem in Western countries. Scandinavia has the world's 19 highest incidence rates of hip fractures⁽¹⁾. Traditionally the Northern European countries have had a

20 high dietary intake of cow's milk and high lactase persistence⁽²⁾. Cow's milk is a plentiful source of

21 substrates for bone and muscle (energy, protein, calcium and phosphorus) in addition to riboflavin,

vitamin B12, iodine, potassium and other minerals $^{(3; 4)}$. Food-based dietary guidelines in many

23 countries, including Norway, the UK, the USA, Canada and Australia, recommend daily use of low-

fat milk and dairy products^(5; 6). Milk is promoted as a calcium source to osteoporosis patients⁽⁷⁾.

Although calcium sufficiency is a key component for skeletal integrity, a link between dietary
calcium intake or milk/dairy intake and fracture risk has been difficult to detect in epidemiologic
studies^(8; 9; 10; 11).

An earlier meta-analysis of seven cohort studies found no association between milk intake 28 29 and risk of hip fracture in women and a suggestive (non-significant) protective association in men⁽¹²⁾. An updated meta-analysis published in 2018 with data from cohort studies found no 30 31 association between milk intake and risk of hip fracture in genders combined, with high heterogeneity between studies⁽¹³⁾. Interestingly, a long-term follow-up of two large Swedish cohorts 32 33 (included in the most recent meta-analysis) identified a clear linear trend of higher risk of hip fracture with higher milk consumption in 61,400 women, while soured milk and yogurt showed the 34 opposite pattern. No association was observed in 45,300 men⁽¹⁴⁾. An updated analysis of two US 35 cohorts of 80,600 women and 43,300 men followed for an average of 20.8 and 17.5 years, 36 respectively, found an overall reduced risk of hip fracture with increasing milk intake, and stratified 37 analyses revealed that the reduced risk was most evident in obese men and women⁽¹⁵⁾. Thus, the 38 evidence is conflicting and the role of milk in bone health remains $unclear^{(16)}$. 39 40 The aim of the present study was to study the association between milk consumption and

41 risk of hip fracture in the Norwegian population.

43 **METHODS**

44 Study population

Data from regional population-based health studies across Norway were used. These were analysed 45 as two separate cohorts due to differences in periods of data collection, age range of participants,

- 46
- 47 format of questionnaire data including milk consumption and available covariates.

48 The data from the Norwegian Counties Study included the third wave of large 49 cardiovascular health screenings carried out in the west coast county of Sogn og Fjordane 1985-86, the inland county of Oppland 1986-88 and the northernmost county of Finnmark 1987-88⁽¹⁷⁾. The 50 51 study population for analysis comprised those who attended the screening, responded to the 52 question about milk, had valid weight, height and smoking data, and were 50 years and older and residing in Norway as of 1st January 1994 (start of follow-up). 53

54 The Five Counties Study consists of harmonised data from regional multi-purpose health 55 examination surveys in five counties, performed by the National Health Screening Service in 2000-2003 and previously described elsewhere⁽¹⁸⁾. Counties included Oslo (the capital, urban south), 56 57 Oppland, Hedmark (towns and rural areas, south), Troms and Finnmark (towns and rural areas, 58 north). The study population for analysis comprised participants 50 years and older who attended 59 the screening, responded to the question about milk and had valid weight, height and smoking data. 60

61 Data collected at screening

In all health studies, the participants' height and weight were measured by standardised tools. Self-62 reported information about lifestyle factors such as health and disease, smoking and physical 63 activity was collected through questionnaires. 64

65

66 *Milk consumption and diet*

In the Norwegian Counties Study, diet was assessed through a 60-item semi-quantitative food 67 68 frequency questionnaire (FFQ) which enabled calculation of nutrient intake. The FFQ was designed 69 to cover dietary risk factors for cardiovascular disease and had an emphasis on fat composition, but 70 is also suitable for studying other outcomes assumed to be related to dietary components covered by 71 the questionnaire. A validation of the FFQ against 24-hour recalls showed satisfactory agreement for common foods that are used daily, such as $milk^{(19)}$. The question about milk consumption was 72 73 posed as follows: "How many glasses of milk do you usually drink per day?" with seven response 74 categories ranging from "Do not drink milk or less than 1 glass per day" to "6 glasses or more per 75 day". These response categories were recoded into a discrete numeric variable with values ranging 76 from 0 to 6. For analyses with categories, the three highest response categories were recoded into 77 one category indicating "4 or more glasses per day". This was due to a low proportion responding to the higher categories, and for comparability with the second cohort (see below) and with previous studies. The milk question did not specify which type of milk to report (sweet or soured). A separate question asked about what type of milk the respondent usually drank, separating milk types according to fat content.

82 In the Five Counties Study, only a few selected questions about diet were included, which did not allow energy and nutrient calculations. Information about milk consumption was obtained 83 84 through three questions discriminating between types of milk according to fat content. Sweet and 85 soured milk, kefir, and yogurt were combined in the same questions and could not be separated. The 86 questions asked for number of glasses consumed per day, with the following five frequency categories: "Seldom/never", "1-6 gl/wk", "1 gl/day", "2-3 gl/day" and "4 glasses or more per day". 87 This was recoded into a numeric variable indicating frequency with the values 0, 0.5, 1, 2.5, and 4 88 89 glasses per day, respectively. When summing up the three milk questions, the resulting values 90 ranged from 0 to 12 glasses per day. For analyses with categories, this summed variable was 91 recoded into five categories ranging from "0" to "4 or more glasses per day". The volume of a glass 92 of milk was not specified in either cohort, but the standard volume of a glass of milk at the time of the data collections was $1.50 \text{ dl} (150 \text{ g milk})^{(20)}$. Thus, the highest category may be considered to 93 94 represent an intake level of ≥ 6 dl per day.

95

96 *Hip fracture outcome*

Incident hip fractures were identified by linkage to the NOREPOS hip fracture database (NORHip).
This database includes information on all proximal femur fractures (femoral neck, trochanter and
sub-trochanter) treated in hospitals in Norway 1994-2013, retrieved from the hospitals' patient
administrative systems (until 2008) and from the Norwegian Patient Register (2008-2013)^(21; 22).
Data on hospital admissions with hip fracture before 1994 were not available as this was the first
year electronic patient administrative systems were used in all hospitals.

103

104 *Demographic variables*

105 The National Registry provided dates for deaths and emigration. Data on marital status and attained 106 education level were obtained from Statistics Norway. Education level from the 1990 Norwegian 107 Population and Housing Census was used for participants in the Norwegian Counties Study, while 108 education level from the 2001 Census was used for participants in the Five Counties Study.

109

110 Follow-up

111 For participants in the Norwegian Counties Study, follow-up started 1st January 1994, while for

112 participants in the Five Counties Study, follow-up started at the date of participation. The subjects

were followed until the date of their first incident hip fracture, death, emigration or 31st December
2013, whichever came first.

- 115
- 116 *Statistical analysis*

Statistical analyses were performed in R⁽²³⁾ for Windows, version 3.4.3. Baseline characteristics 117 across levels of milk consumption were tested by analysis of variance (ANOVA) for continuous 118 119 variables and chi square test for categorical variables. Cox proportional hazards regression using attained age as time scale^(24; 25) was performed to estimate hazard ratios (HR) with 95% confidence 120 intervals (CI) for hip fracture according to levels of milk consumption. Plots and tests of Schoenfeld 121 residuals against time⁽²⁶⁾ indicated that the proportional hazards assumption was met for milk 122 consumption. To investigate a potential linear association with hip fracture, milk consumption was 123 124 entered as number of glasses of milk per day on a continuous scale. To investigate a potential 125 nonlinear association between milk consumption and hip fracture, predefined analyses were also 126 performed using penalised splines of milk consumption as the explanatory variable, and using 127 categories of milk consumption ranging from <1 glass per day to 4 or more glasses per day, with 1 128 glass per day as reference category. Analyses were performed in genders combined and separately 129 for men and women. Tests were considered statistically significant at the 0.05 level. For both 130 cohorts, three models with increasing statistical adjustment were constructed. The basic model 131 (model 1) included adjustment for county (and gender in gender-combined analyses). Age was not 132 entered as a covariate, as attained age defined the time scale in the Cox models, but including adjustment for age at baseline participation (continuous) produced virtually identical results (data 133 134 not shown). The intermediate model (model 2) included additional adjustment for BMI (kg/m², 135 continuous) and cigarette smoking (five categories: Never-smoker, ex-smoker, currently smoking 136 less than 15 cigarettes per day, currently smoking 15 or more cigarettes per day, and currently smoking with number of cigarettes per day not reported). The fully adjusted model (model 3) also 137 138 included the following additional covariates: Regular use of any vitamin supplement or cod liver 139 oil, respectively (yes/no), comorbidity (mean number of self-reported chronic diseases among the 140 following options: myocardial infarction, angina, stroke, diabetes, treated hypertension), body 141 height (cm, continuous), physical activity during leisure time (four response categories 142 dichotomised into sedentary vs. moderately active/ active/ very active), marital status (dichotomised 143 into married vs. unmarried/ widowed/ divorced/ separated), education level (nine levels recoded 144 into five levels ranging from primary school or shorter to postgraduate education). Energy intake estimated from the FFQ in kJ/day (continuous) was available in the Norwegian Counties Study 145 146 only, while use of acid suppressing drugs including proton pump inhibitors and H2 receptor antagonists (yes/no) and self-rated health in four response categories ranging from poor to very 147

- 148 good were available in the Five Counties Study only. In the Norwegian Counties Study some
- 149 participants had missing data for education (1.1%), energy intake (0.3%), physical activity (0.08%),
- and marital status (0.04%). In the Five Counties study some participants had missing data for
- 151 physical activity (3.1%), self-rated health (1.5%), education (1.3%), and marital status (0.4%). For
- these covariates, missing values were treated as a separate category in the fully adjusted Cox
- 153 regression analyses.
- 154 Statistical interaction was tested in the fully adjusted models by including interaction terms 155 for milk consumption as continuous exposure and each of the respective variables gender, county 156 and BMI. Subgroup analyses were performed in strata of BMI and gender, based on the previous 157 finding of an interaction between BMI and milk in the Nurses' Health Study⁽¹⁵⁾. For these subgroup 158 analyses, BMI was divided in three categories using the cutoffs 24 and 27 kg/m², which
- 159 corresponded closely to the tertile limits of BMI in the Norwegian Counties Study.
- In the Five Counties Study, sensitivity analyses were performed for follow-up time <6 years and \geq 6 years, corresponding to the 10-percentile of follow-up time, to investigate whether any potential influence of milk consumption may be more relevant for fractures occurring closer in time to the measurement of dietary exposure. In addition, we performed a sensitivity analysis limited to participants aged 75 years and older at participation in the health study. In the Norwegian Counties Study, the age of participants was too low and the follow-up time for the majority of participants too long to obtain meaningful results from such analyses.
- 167
- 168 *Ethical approvals*
- 169 The study and the data linkages have been approved by the Norwegian Data Protection Authority,
- 170 the Regional Committee for Medical and Health Research Ethics, the Directorate of Health,
- 171 Statistics Norway, and the Norwegian Institute of Public Health.
- 172

173 **RESULTS**

174 Baseline characteristics, milk consumption and incident hip fractures

- 175 Of the 35,165 eligible participants in the Norwegian Counties Study, the study population for
- analysis constituted 35,114 individuals (99.9% of participants) with valid height, weight and
- 177 smoking data (51% women). Median age at screening was 50 years (interquartile range (IQR) 46-53
- 178 years) and mean BMI was 25.7 kg/m². Thirty-six percent were daily smokers and 18% were
- 179 sedentary during leisure time. Mean (standard deviation (SD)) number of glasses of milk consumed
- 180 per day was 2.6 (1.5) corresponding to 390 g milk/day in men and 1.7 (1.1) corresponding to 255 g

181 milk/day in women. In both genders, those reporting the highest milk consumption had the highest

- 182 energy intake, a lower proportion were married, a lower proportion had completed secondary
- 183 education, and a higher proportion were smokers (Table 1). Among men, there was a slightly higher
- 184 proportion of sedentary among those consuming 0 or less than 1 glass of milk per day, whereas
- among women, the high-consumers of milk were equally sedentary as the low-consumers. In men,
- 186 603 incident hip fractures occurred during 291,335 person-years of follow-up while in women
- 187 1,262 incident hip fractures occurred during 321,683 person-years of follow-up. Median age at hip

188 fracture was 72 years (IQR 67-77 years).

- Of the 23,415 eligible participants in the Five Counties Study, the study population for 189 analysis constituted 23,298 individuals (99.5% of participants) with valid height, weight and 190 smoking data (54% women). Median age at screening was 62 years (IQR 60-75 years) and mean 191 192 BMI was 27.0 kg/m². Twenty-six percent were daily smokers and 16% were sedentary during 193 leisure time. Mean (SD) number of glasses of milk consumed per day was 1.5 (1.2) corresponding 194 to 225 g milk/day in men and 1.2 (1.1) corresponding to 180 g milk/day in women. In both genders, 195 those reporting the highest milk consumption had a higher prevalence of daily smokers, a lower 196 proportion were married, and a lower proportion had completed secondary education. Among 197 women, those with the highest milk consumption were also older and more sedentary (Table 2). In 198 men, 473 incident hip fractures occurred during 114,876 person-years of follow-up while in women, 199 993 incident hip fractures occurred during 138,120 person-years of follow-up. Median age at hip 200 fracture was 81 years (IQR 76-85 years).
- 201

202 Milk consumption and hip fracture: The Norwegian Counties Study

- 203 In the Norwegian Counties study, overall HR for hip fracture per daily glass of milk (type not
- specified) in the fully adjusted model was 0.99 (95% CI 0.96, 1.04) and it was not statistically
- 205 significant in either gender: HR 0.97 (95% CI 0.92, 1.03) in men and HR 1.02 (95% CI 0.96, 1.07)
- in women (Table 3). Fully adjusted Cox regression with splines of milk consumption was not

- significant in men (p=0.55 for linear and p=0.27 for nonlinear association) nor in women (p=0.36
- 208 for linear and p=0.55 for nonlinear association). Compared with those drinking 1 glass of milk per
- 209 day, HR was non-significantly increased in those drinking 0 or <1 glass per day in both genders,
- 210 HR 1.33 (95% CI 0.91, 1.93) in men and HR 1.14 (95% CI 0.92, 1.42) in women (Table 3). In men
- 211 drinking 4 or more glasses per day there was no tendency, while in women there was a suggested
- 212 increased risk among the high-milk-consumers which was attenuated after adjustment for
- 213 confounders; HR 1.15 (95% CI 0.92, 1.43) (Table 3).
- 214

215 Milk consumption and hip fracture: The Five Counties Study

- 216 In the Five Counties Study, overall HR for hip fractures per daily glass of milk (including sweet and
- soured milk, kefir, and yogurt) in the fully adjusted model (model 3) was 1.02 (95% CI 0.97, 1.06)
- and it was not statistically significant in either gender: HR 0.99 (95% CI 0.92, 1.07) in men, and HR
- 219 1.02 (95% CI 0.97, 1.08) in women (Table 4). Fully adjusted Cox regression with splines of milk
- 220 consumption was not significant in men (p=0.65 for linear and p=0.70 for nonlinear association) nor
- in women (p=0.30 for linear and p=0.66 for nonlinear association). For categories of milk intake
- with 1 glass per day as the reference category, there was no association except a non-significant
- 223 23% risk increase in women who reported 4 glasses or more per day (Table 4).
- 224

225 Statistical interaction and subgroup analysis

The interaction term for milk and gender approached statistical significance in the Norwegian 226 227 Counties Study (p=0.08), while there was no interaction with gender in the Five Counties Study (p=0.49). There was no statistical interaction between milk and county in men or women in either 228 229 cohort. Concerning BMI, it showed no interaction with milk consumption in men in either cohort (p=0.80 and p=0.49, respectively). In women, there was a marginally significant interaction 230 231 between milk and BMI among women in the Five Counties Study (p=0.052), and stratified analyses within three categories of BMI suggested an elevated risk of hip fracture per daily glass of milk for 232 those with BMI< 24 kg/m² (HR 1.09, 95% CI 0.99, 1.19) but not for those with BMI \ge 27 kg/m² 233 234 (HR 0.95, 95% CI 0.86, 1.05) (Supplementary Table 1). In subgroup analyses with 1 glass per day 235 as the reference category, women in the Norwegian Counties Study with $BMI < 24 \text{ kg/m}^2$ who reported a consumption of 4 or more glasses of milk per day had a statistically significant HR of 236 237 1.38 (95% CI 1.02, 1.88) for hip fracture. In the Five Counties Study, the increased HR in the low-238 BMI high-milk consuming women was not statically significant (HR 1.60, 95% CI 0.94, 2.73 in the fully adjusted model). The subgroup of women with BMI<24 kg/m² who reported a milk intake of 4 239 240 glasses or more per day constituted 3.2% of women in the Norwegian Counties Study and 0.7% of

- 241 women in the Five Counties Study. This group was also characterised by a higher smoking
- 242 prevalence, a higher proportion being sedentary during leisure time, and poorer self-rated health.
- 243
- 244 Sensitivity analyses
- 245 Cox regression confined to participants aged 75 years and older at baseline in the Five Counties
- 246 Study yielded similar results as in the full cohort. In separate analyses according to length of
- follow-up in the Five Counties Study, an increased risk of hip fracture in high milk consuming
- 248 women was observed only in the shorter term (<6 years). While there was not a significant linear
- trend, women reporting 4 or more glasses of milk per day (299 women, 16 hip fractures) had HR
- 250 1.78 (95% CI 1.05, 3.01) for hip fracture compared with the reference category (4,577 women, 124
- 251 hip fractures) in the fully adjusted model. There was no association for follow-up > 6 years, neither
- a linear trend nor in categories of milk consumption. In men, separate Cox regression according to
- 253 follow-up time did not yield any substantially different results.

cequ

254

255 **DISCUSSION**

In this prospective study using two different cohorts linked with incident hip fractures from patient administrative systems over a 20-year period, we found no clear association between milk consumption and risk of hip fracture.

259 A previous follow-up to the first wave of the Norwegian Counties Study with 210 incident hip fractures (154 in women and 56 in men) identified in medical records during average follow-up 260 261 13.8 years, found a reduced risk of hip fracture in men with higher milk consumption and no association in women⁽²⁷⁾. In men, multivariable adjusted RR of hip fracture was 0.46 (95% CI 0.22, 262 263 0.98) in those drinking 4 glasses of milk per day or more (11 hip fractures) compared with those 264 drinking one glass per day or less. The corresponding RR in women was 0.83 (95% CI 0.44, 1.56), 265 also with 11 hip fractures in the highest milk consumption category. There was no linear trend 266 through increasing milk consumption. Although we do not have a clear explanation for the 267 discrepant findings of that study and the current results, it should be noted that the previous analysis was performed in the cohort participating in the first wave during the late 1970s, with short follow-268 269 up, few fractures and a younger study population (mean age at hip fracture 57 years in women and 270 55 years in men).

Findings from other countries have been conflicting. In 2011 a meta-analysis⁽¹²⁾ summed up the results of cohort studies investigating the association between milk intake and hip fracture. Based on six studies with 195,102 women and 3574 incident hip fractures, pooled RR per glass of milk per day in women was 0.99 (95% CI 0.96, 1.02), with low heterogeneity. In men, based on three studies with 75,149 men and 195 hip fractures, pooled RR per daily glass of milk was 0.91 (95% CI 0.81, 1.01). The authors concluded that there was no overall association between milk intake and risk of hip fracture in women, but that more data were needed in men.

278 However, interestingly, a different conclusion was arrived at in analyses from the Swedish 279 Mammography Cohort (SMC) with n=61,433 women followed for an average of 20 years resulting in 4,259 hip fractures, and the Cohort of Swedish Men with n=45,339 men followed for an average 280 of 11 years resulting in 1,166 hip fractures⁽¹⁴⁾. While no association was found between milk 281 282 consumption and risk of hip fracture in men, a, higher milk consumption was associated with 283 increased risk of hip fracture in women, with HR 1.09 (95% CI 1.05, 1.13) per glass of milk per 284 day. Hazard ratio for three or more glasses per day vs. one glass or less was 1.60 (95% CI 1.39, 285 1.84) while there was an increased risk even at 1-2 glasses per day with HR 1.19 (95% CI 1.11, 286 1.28). The volume of a glass was defined as 200 g milk. These findings pertained to sweet milk, 287 while a higher intake of soured milk and yogurt showed the opposite pattern and was associated 288 with 8% reduced risk per 200 g higher consumption per day. In an updated analysis in the SMC, these risk patterns persisted after stratification for fruit and vegetable intake⁽²⁸⁾. Moreover, the 289

290 associations did not differ across two BMI strata (divided at 25 kg/m²), however BMI was based on 291 self-reported height and weight⁽²⁸⁾. The SMC is comparable to the cohort of women participating in the Norwegian Counties Study with regard to the time of baseline data collection (1987-90), age 292 293 distribution, magnitude of milk consumption (mean 240 g/day), and also in Sweden the smoking 294 prevalence was higher among the women with the highest milk consumption. In addition, there was more comorbidity in the highest milk consumption category in the SMC⁽¹⁴⁾. Results from the two 295 296 Swedish cohorts were included in a meta-analysis published in 2018 that covered data from ten 297 cohorts. The meta-analysis found no association between milk intake and risk of hip fracture in genders combined⁽¹³⁾. There was high heterogeneity between studies, which is a general 298 299 shortcoming when performing meta-analyses of cohort studies in nutritional research.

300 Results from an updated follow-up to the Nurses' Health Study and the Health Professionals' Follow-up Study in US women and men was published in 2017⁽¹⁵⁾ and were not 301 included in the abovementioned meta-analysis. The data included 2,138 hip fractures in 80,600 302 women and 694 hip fractures in 43,300 men during an average follow-up of 20.8 years and 17.5 303 304 years, respectively. RR 0.92 (95% CI 0.87, 0.97) per daily glass of milk consumed was found in 305 genders combined. The hip fracture outcome was based on self-report. There was interaction 306 between milk drinking and BMI (based on self-reported weight and height), and the reduced risk 307 was most evident at BMI 30 kg/m² or higher in both men and women.

308 The possible causes for the conflicting findings between different cohorts are not understood, but have been intensely debated⁽²⁹⁾. Studies have predominantly been performed in 309 310 Caucasian populations living in Europe and the US. Milk drinking may represent different 311 exposures across populations due to e.g. differences in fortification practices. Unlike the 312 Scandinavian countries, the US has a long history of vitamin D fortification of milk⁽³⁰⁾. Different findings may also result from methodologic challenges. Participants' age, proximity in time 313 314 between measurement of exposure and outcome, exposure range for milk consumption, mode of 315 fracture identification (registry linkage vs. self-report), data collection method for height and weight 316 (measured vs. self-reported), and the available confounders differ between studies.

317 In the present study, subgroup analyses in women with low BMI at baseline ($< 24 \text{ kg/m}^2$) 318 showed that hazard ratios for hip fracture in those drinking 4 or more glasses per day were 319 increased compared with the reference category reporting 1 glass per day in both cohorts, while 320 there was no trend through increasing milk consumption. The associations were attenuated, but not 321 eliminated, by adjustment for confounders. The low-BMI high-milk consumers constituted a low 322 proportion of the population; 3.2% and 0.7% of women in the two respective cohorts. They were to 323 a higher degree characterised by behaviour related to increased fracture risk, including high prevalence of cigarette smoking, physical inactivity, and poor self-rated health. We cannot rule out 324

that our results are influenced by residual confounding introducing a spurious positive association between milk consumption and hip fracture, and that a high milk intake may be an indicator of poor health in this subgroup of women rather than representing a causal risk factor for hip fracture. For example, it could be speculated that the increased risk associated with a high milk intake in the lowweight women could be related to illness associated with gastrointestinal complaints. Attempts were made to capture the potential influence of such illness by including information on use of acidsuppressing drugs, but this did not affect our associations.

332 Also, sensitivity analyses in the Five Counties study population suggested that an increased 333 risk in high milk consuming women was confined to shorter-term follow-up. This may suggest that 334 self-reported milk consumption represents a more valid estimate of exposure the closer to event it is 335 measured. However, it may also reflect that an effect is more detectable in the older and frailer 336 segment of the population, and that the characteristics of the population at risk changes during 337 follow-up due to selection. The subcohort who were still alive and had not fractured within six 338 years after baseline examination had slightly lower average age, higher average BMI, better self-339 rated health and lower smoking prevalence at participation when compared with the full cohort.

340

341 Range of exposure and portion sizes

Exposure classification was based on questionnaire data indicating number of glasses of milk 342 343 usually consumed. The volume of a glass was not specified in the milk question in either study. Although standard portion sizes have changed over time⁽³¹⁾, a common standard portion of a glass 344 of milk at the time of the data collections was 1.50 dl (150 g milk)⁽²⁰⁾. The highest category of 4 or 345 more glasses per day is thus comparable to the highest consumption category in the analysis of the 346 Swedish cohorts⁽¹⁴⁾, corresponding to 6 dl or more per day. In the SMC, mean daily milk 347 consumption at baseline in 1987-90 was 240 g/day, which is similar to the mean daily milk 348 349 consumption of women in the Norwegian Counties Study 1985-88 (estimated to 255 g/day). In the 350 US cohorts, the average intake in 1986 was slightly lower than that in the Norwegian Counties 351 Study, with mean milk consumption reported to be 6.3 servings à 240 ml per week, corresponding 352 to an average of 216 ml per day $^{(15)}$.

353

354 Strengths and limitations

355 The population-based design is a strength of the present study. Attendance rates were high in the

third wave of the Norwegian Counties Study: 78%, 86% and 87% in the different counties.

357 Attendance rates in the more recent health studies in five counties were somewhat lower and varied

from 50% in women aged 75-76 in Oslo to 75% in women aged 60 in Troms and Oppland.

359 Questionnaires were standardised and data were harmonised across studies. Of particular interest,

the height and weight measurements were standardised and performed in the same way across all
 health studies included in both cohorts. Another important strength is the objective outcome
 measure obtained from patient administrative databases in all hospitals in Norway, that have been
 carefully quality assured^(21; 22).

364 A limitation of both cohorts is the small variation in reported daily milk intake. The participants were homogenous with regard to milk: The large majority reported around 1 glass per 365 366 day in women, while the proportion who reported to drink 4 or more glasses of milk per day was 367 very low. As milk consumption in Norway as well as other countries have decreased steadily over 368 time, more recent assessments of effects of variations in milk intake on health outcomes will be 369 hampered by a narrow exposure range, making it more difficult to detect potential associations. 370 Also, we were not able to separate fracture risk in individuals who never drank milk from that in 371 individuals who drank milk infrequently, since the lowest response category in the two 372 questionnaires was defined as "Do not drink milk or less than 1 glass per day" and "Seldom/never".

Another limitation in both cohorts was that sweet and soured milk could not be studied 373 374 separately, as the wording of the questionnaire combined these types of milk (in addition to yogurt 375 in the Five Counties study) into the same questions. In the SMC, a higher intake of sweet milk 376 entailed increased risk of hip fracture, while a higher intake of soured milk and yogurt showed the opposite pattern with fracture risk^(14; 28). We could not disentangle an effect of soured milk in our 377 378 data. However, sweet milk is the predominant type of milk consumed in Norway. At the time of the 379 data collections (1985-88 and 2000-02), soured milk constituted only 6 to 7% of milk consumption 380 in Norway (personal communication, Norwegian Dairy Council).

381 In the Norwegian Counties study, limitations also included a relatively young population at 382 baseline, with a long average time period from baseline measurements to occurrence of hip 383 fractures. Most hip fractures occurred towards the end of the follow-up period, with median age 72 years at hip fracture. Dietary habits and other lifestyle factors and behaviour may have changed 384 during the long follow-up period and thus contributed to dilute associations. Another limitation is 385 386 that follow-up with regard to hip fracture did not commence until 1 January 1994, which was the 387 first year all hospitals nationwide used electronic patient administrative systems. Any hip fractures 388 occurring in the period from screening until start of follow-up (median 7, maximum 9 years) have 389 not been captured and these participants will have been misclassified unless they suffered a second 390 hip fracture during the subsequent years. However, we expect few hip fractures to have occurred in 391 this period due to the low average age (median 50 years at participation), and we do not believe that 392 this has influenced the results. Regardless of limitations, the results are supported by the similar 393 results in the Five Counties Study, performed more recently and with an older age distribution 394 (median age 62 years at participation and 81 years at hip fracture).

- 395 In the Five Counties Study, a limitation is the lack of data about energy intake since the 396 questionnaires included only a few selected dietary questions. The semi-quantitative FFO in the 397 Norwegian Counties study did not cover the entire diet, but yielded meaningful results concerning a 398 positive association between milk consumption and calculated energy intake. Adjustment for energy 399 intake in multivariable Cox regression had a small but not unimportant influence on the estimates 400 for the milk-hip fracture association: In women, the hazard ratio changed from 1.20 (95% CI 0.97, 401 1.48) to 1.15 (95% CI 0.92, 1.43) for 4+ vs. 1 glass/day when including adjustment for energy 402 intake.
- 403

404 *Conclusions and implications*

Results from our two cohorts of large population-based regional health studies in Norway did not support a clear protective nor risk-increasing association between milk consumption in adult life and later hip fractures. Milk and dairy represents an important source of energy, protein, calcium and a number of other important nutrients, and based on current knowledge it should not be discouraged to the at-risk population.

410

411 ACKNOWLEDGMENTS

412 Data from the Norwegian Patient Register has been used in this publication. The interpretation and 413 reporting of these data are the sole responsibility of the authors, and no endorsement by the 414 Norwegian Directorate of Health is intended nor should be inferred. Staff in the Norwegian Institute 415 of Public Health (previously the National Health Screening Service) and Statistics Norway are 416 acknowledged for data collection and linkage to hip fracture data. We thank Jon Marius Grasto 417 Wickmann at the Norwegian Institute of Public Health for his valuable contribution in data 418 management and quality assurance.

419

420 CONFLICT OF INTEREST

421 None.

422

423 AUTHORSHIP

424 KH reviewed the literature, performed the data analyses and drafted the manuscript. KH, HEM,

- 425 TKO and AJS contributed in the acquisition and quality assurance of hip fracture data. IL
- 426 performed the calculations of energy and nutrient intakes in the Norwegian Counties Study. HEM,
- 427 IL, DF, TKO and AJS critically revised the manuscript for intellectual content. All co-authors have
- 428 approved the final version of the manuscript and take responsibility for its integrity.

506 **Table 2.** Baseline characteristics across glasses of milk* consumed per day in the study population from regional health studies in five counties in 2000-2002

SD, standard deviation; BMI, body mass index

All p values <0.05 except height in men (p=0.71), BMI in women (p=0.08), self-reported chronic diseases in women (p=0.13), self-rated health in women (p=0.14), vitamin/mineral supplements (p=0.22 in men, p=0.07 in

women) and acid suppressing drugs (p=0.51 in men, p=0.11 in women). Continuous variables were compared using ANOVA and categorical variables were compared using chi square test.

* The milk questions included sweet and sourced milk, kefir, and yogurt. Frequencies were summed from three questions according to the following frequency definitions: seldom/never=0; 1-6 gl/wk=0.5; 1 gl/day=1; 2-3 gl/day=2.5; 4 or more gl/day=4.

- † Among the options: myocardial infarction, angina, stroke, diabetes, treated hypertension
- 13 ‡ Self-reported use of histamine-2 receptor antagonists and proton pump inhibitors
- 4 § Completed secondary education (baccalauréat) or higher vs. first year of high school or lower, according to data from the Norwegian Population and Housing Census 2001 (Statistics Norway)
