Abstract

Background: Obesity is an established risk factor for several cancers. Adult weight gain has been associated with increased cancer risk, but studies on timing and duration of adult weight gain are relatively scarce. We examined the impact of BMI (body mass index) and weight changes over time, as well as timing and duration of excess weight, on obesity- and non-obesity-related cancers.

Methods: We pooled health data from six European cohorts, and included 221,274 individuals with two or more height and weight measurements during 1972-2014. Several BMI and weight measures were constructed. Cancer cases were identified through linkage with national cancer registries. Hazard ratios (HRs) of cancer with 95% confidence intervals (CIs) were derived from time-dependent Cox regression models.

Results: During follow-up, 27,881 cancer cases were diagnosed; 9,761 were obesity-related. The HR of all obesity-related cancers increased with increasing BMI at first and last measurement, maximum BMI, and longer duration of overweight (males only) and obesity. Participants being overweight before age 40 had an HR of obesity-related cancers of 1.16 (95%CI 1.02, 1.32) and 1.15 (95%CI 1.04, 1.27) in males and females, respectively, comparing those not overweight. The risk increase was particularly high for endometrial (70%), male renal cell (58%), and male colon cancer (29%). No positive associations were seen for cancers not regarded as obesity-related.

Conclusions: Adult weight gain was associated with increased risk of several major cancers. The degree, timing and duration of overweight and obesity also seemed to be important. Preventing weight gain may reduce the cancer risk.

Introduction

Obesity is a major global health challenge. Worldwide, the overall prevalence of obesity (body mass index (BMI) ≥ 30 kg/m²) among adult was 12% in 2015, and 5.4% of BMI-related deaths were due to cancer among obese persons.¹ In 2016, an IARC (International Agency for Research on Cancer) evaluation confirmed that excess body fatness was causally related to cancers of the oesophagus (adenocarcinoma), colon and rectum, kidney (renal cell carcinoma), endometrium and breast in postmenopausal women.² In addition, the IARC evaluation identified eight more cancers as causally related to excess body fat.² A 2017 umbrella review of almost 200 meta-analyses largely confirmed these findings.³

In a 2015 meta-analysis of prospective observational studies, each 5 kg increase in adult weight gain was associated with increased risk of postmenopausal breast (11%), endometrial (39%) and ovarian cancer (13%), and male colon cancer (9%).⁴ A longitudinal study of postmenopausal women in the US showed that longer duration of overweight and obesity during adulthood increased the incidence of obesity-related cancers combined, postmenopausal breast cancer, and colon, endometrial and kidney cancer.⁵ Also, a follow-up study from 2017 demonstrated a dose-response association of weight gain with several cancers.⁶

The 2018 report on Body fatness and weight gain and the risk of cancer from the World Cancer Research Fund concluded, however, that there was strong evidence of an association between weight gain in adulthood and increased risk of postmenopausal breast cancer only. Consequently, more research is needed on the association between weight gain and other obesity-related cancers.⁷ Also studies on timing and duration of adult weight gain are relatively scarce.⁸⁻¹⁰

1

19 **Material and Methods**

20 ***The Me-Can 2.0 Project***

21
22 The Me-Can 2.0 project is an expansion of the previous Me-Can 1.0 project,¹¹ and pools data
23
24 from six cohorts in Austria (Vorarlberg Health Monitoring and Prevention Programme),
25
26 Norway (Norwegian Counties Study, Age 40 Programme, and Oslo Study I), and Sweden
27
28 (Västerbotten Intervention Programme and Malmö Preventive Project). All individuals in the
29
30 cohorts have undergone one or more health examination(s), including measurements of
31
32 height, weight, and circulating levels of glucose and triglycerides. We had no information
33
34 available on ethnicity or place of birth.
35
36
37
38
39
40
41

42 In this study, we only included adults with two or more height (≥ 100 cm) and
43
44 weight (≥ 35 kg) measurements during 1972-2014, obtained at least three years apart, and
45
46 before the first cancer diagnosis ($n=221,274$) (Figure 1).
47
48
49

50 ***Exposure***

51
52 Height and weight were measured at each health examination.¹¹ BMI was calculated as
53
54 weight (kg) divided by the squared value of height (m), and categorized according to the
55
56 World Health Organization (WHO);¹² BMI (kg/m^2) <18.5 (underweight), 18.5-24.9 (normal
57
58
59
60

1
2
3 weight), 25.0-29.9 (overweight), ≥ 30.0 (obese). We used the second measurement as
4
5
6 baseline for follow-up.
7

8 Several BMI and weight measures were constructed:
9

- 10 1. BMI at first and last measurement.
- 11 2. Maximum BMI measured.
- 12 3. BMI change since first measurement.
- 13 4. Weight change since first measurement.
- 14 5. Cumulated overweight-years (OWYs) calculated as the number of years being
15

60
overweight (BMI 25.0-29.9 kg/m²) since first measurement, assuming a linear change
in BMI between measurements. All BMI measurements and all years between first
and last measurement were included.
6. Cumulated obesity-years (OBYs) calculated in a similar way as in point 5 for BMI
 ≥ 30.0 kg/m².
7. Based on the first two measurements, five BMI-trajectories were made (including
92% of the study population).
8. Age at first measurement with BMI ≥ 25 kg/m² (<40, 40-49 years).

Outcome

After the second health examination, the individuals were followed until their first cancer, emigration, death, or end of follow-up (Austria and Sweden; 2014, Norway; 2012), whichever occurred first. Incident cancers were identified through linkages with national cancer registries.¹³⁻¹⁵ In Norway and Sweden, the cohorts were also linked to population registries for vital status. Cancers were coded according to ICD-7/10, ICD-O-2/3 and

1
2
3 SNOMED for topography and morphology. We studied all obesity-related cancers combined
4
5 (cancers of the oesophagus (adenocarcinoma), gastric cardia, colon, rectum, liver,
6
7 gallbladder, pancreas, breast (postmenopausal), endometrium, ovary, kidney (renal cell),
8
9 and thyroid gland, and meningioma and multiple myeloma) and specific obesity-related
10
11 cancers, such as breast (postmenopausal), endometrial, colon, and renal cell cancer.²
12
13
14 Results for rectal, pancreatic, ovarian and other obesity-related cancers as well as non-
15
16 obesity-related cancers are presented in the Supplementary Material.
17
18
19

20 21 **Potential Confounders**

22
23 The following factors were considered potential confounders and were adjusted for in the
24
25 analyses: Smoking status (never, former, current smokers (divided into pack-years, <5, 5-
26
27 13.4, ≥13.5 pack-years or missing)), parity (0, 1, 2, 3, ≥4), age at first birth (<20, 20-24, 25-29,
28
29 30-34, ≥35), physical activity (sedentary, light, moderate), education (Norway; compulsory,
30
31 intermediate, tertiary, and Sweden; elementary school, junior secondary school, upper
32
33 secondary school and university education), and triglycerides-glucose index (TyG index; a
34
35 measure of insulin resistance)^{16;17} (<7, 7-7.9, 8-8.4, 8.5-8.9, ≥9). Information on smoking
36
37 status was available in all cohorts, whereas information on reproductive history (Norwegian
38
39 cohorts), physical activity and education (Norwegian and Swedish cohorts), and TyG index
40
41 (mostly Austrian and Swedish cohorts) was only available in some. Smoking status was
42
43 included in all models, whereas the other potential confounders were included in cancer-
44
45 specific models.
46
47
48
49
50
51

52 53 **Statistical Analysis**

54
55 Cox regression models with age as the time metric were fitted to obtain hazard ratios (HRs)
56
57 with 95% confidence intervals (95% CIs). Tests for linear trend over BMI-categories were
58
59
60

1
2
3 conducted using the BMI-variables as continuous variables. Statistical tests were two-sided.
4
5 Some of the included variables were time-dependent; smoking status, BMI at last
6
7 measurement, maximum BMI, BMI change, weight change, OWY, OBY and age at first
8
9 measurement with BMI \geq 25 changed at each measurement. The BMI and weight metrics
10
11 were first included one at a time in separate models, except for OWY and OBY being
12
13 included simultaneously. Thereafter, some of the metrics (BMI at last measurement,
14
15 maximum BMI, BMI change, weight change, OWY and OBY) were included in models with
16
17 adjustment for BMI at first measurement.
18
19
20
21
22

23 All models were adjusted for age at first measurement and at baseline,
24
25 country, and smoking status. Cancer-specific adjustments were made in sensitivity analyses
26
27 within the cohorts. Postmenopausal breast, endometrial, and ovarian cancer were
28
29 additionally adjusted for parity, age at first birth, physical activity and education. Colon and
30
31 pancreatic cancer were additionally adjusted for TyG index, physical activity and education.
32
33 To explore the possibility of reverse causation, follow-up started one year after the health
34
35 examinations in separate analyses.
36
37
38
39
40

41 The data was analyzed using IBM SPSS Statistics 23 and Stata/IC 14.0.^{18;19}
42
43

44 ***Ethical and Legal Considerations***

45

46 The Me-Can 2.0 project was approved by ethical committees in the respective countries.
47
48
49

50 **Results**

51

52 The study cohort consisted of 107,422 males and 113,852 females (Table 1). Altogether
53
54 32.4% of the participants had three health examinations, 17.2% participated in four or
55
56 more. Mean number of examinations was 2.7 (range; 2-6). Average time between first and
57
58
59
60

1
2
3 last health examination was 10.3 years (range; 3.0-23.6 years). Mean age at second health
4
5 examination was 48.0 years (range; 19.0-85.0 years), and mean BMI was 25.6 kg/m² (males
6
7 26.0 kg/m²; females 25.2 kg/m²). The majority of the participants (53.8%) were never-
8
9 smokers.
10
11

12
13 The individuals were followed for an average of 17.6 years (range; 0.0 – 36.6
14
15 years), constituting 3.9 million person-years. During follow-up, 27,881 cancers were
16
17 diagnosed; 9,761 (35.0%) were obesity-related (Table 2).
18
19

20
21 The HR of all obesity-related cancers increased with increasing BMI at first and
22
23 last measurement and maximum BMI (Table 3). One unit increase in BMI (HR 1.02, 95%CI
24
25 1.01, 1.03) and 5 kg increase in weight (HR 1.05, 95%CI 1.02, 1.07) were associated with
26
27 increased risk in females. Duration of overweight (males) and obesity over time were also
28
29 associated with risk; the HRs for OWY and OBY were 1.01 (95%CI 1.01, 1.02) and 1.04
30
31 (95%CI 1.03, 1.05) in males, and the HR for OBY was 1.04 (95%CI 1.03, 1.05) in females.
32
33 Males being obese at the first two measurements had an HR of 1.64 (95%CI 1.44, 1.86)
34
35 compared to those with normal BMI. Similar figures were seen in females (HR 1.48, 95%CI
36
37 1.37, 1.61). Those being overweight before age 40 had an HR of obesity-related cancers of
38
39 1.16 (95%CI 1.02, 1.32) and 1.15 (95%CI 1.04, 1.27) in males and females, respectively.
40
41 Excluding postmenopausal breast cancer from the obesity-related cancers, females being
42
43 overweight before age 40 had an HR of 1.27 (95%CI 1.13, 1.44).
44
45
46
47
48
49

50
51 One unit increase in BMI (HR 1.03, 95%CI 1.01, 1.05) and 5 kg increase in
52
53 weight (HR 1.07, 95%CI 1.03, 1.10) were associated with increased risk of postmenopausal
54
55 breast cancer (Table 4). The HR for OBY was 1.02 (95%CI 1.01, 1.03). Those being obese at
56
57
58
59
60

1
2
3 the first two measurements had an HR of 1.22 (95%CI 1.07, 1.39), compared to those with
4
5 normal BMI.
6
7

8 One unit increase in BMI (HR 1.10, 95%CI 1.07, 1.13) and 5 kg increase in
9
10 weight (HR 1.21, 95%CI 1.15, 1.28) were associated with increased risk of endometrial
11
12 cancer (Table 5). The HRs for OWY and OBY were 1.03 (95%CI 1.01, 1.05) and 1.11 (95%CI
13
14 1.09, 1.13), respectively. Those being obese at the first two measurements, overweight at
15
16 first and obese at second, and those being overweight at both measurements were all at
17
18 increased risk. Females being overweight before age 40 had an HR of endometrial cancer of
19
20 1.70 (95%CI 1.31, 2.22).
21
22
23
24
25

26 In males, the HR of colon cancer for OBY was 1.04 (95%CI 1.02, 1.07), and in
27
28 females the HR for OWY and OBY were 1.03 (95%CI 1.01, 1.04) and 1.03 (95%CI 1.01, 1.05),
29
30 respectively (Table 6). Those being obese at the first two measurements, overweight at first
31
32 and obese at second, and those having normal BMI at first and overweight at second
33
34 measurement were all at increased risk. Males being overweight before age 40 had an HR of
35
36 1.29 (95%CI 1.03, 1.62). For rectal cancer, those being obese at the first two measurements,
37
38 were all at increased risk (Table S1).
39
40
41
42
43

44 In males, the HRs of renal cell cancer for OWY and OBY were 1.04 (95%CI 1.01,
45
46 1.07) and 1.08 (95%CI 1.04, 1.11), respectively, and in females the HR for OBY was 1.06
47
48 (95%CI 1.03, 1.09) (Table 7). Those being obese at the first two measurements were at an
49
50 increased risk. Males being overweight before age 40 had an HR of 1.58 (95%CI 1.12, 2.23).
51
52
53

54 The HR of pancreatic cancer for OBY was 1.04 (95%CI 1.01, 1.08) in males
55
56 (Table S2), and those being obese at the first two measurements were at increased risk (HR
57
58 1.81, 95%CI 1.22, 2.68). For ovarian cancer, no associations with the different BMI and
59
60

1
2
3 weight metrics were seen (Table S3). The HR of liver cancer for OBY was 1.09 (95%CI 1.04,
4
5 1.14) in males (Table S4). Those being obese at the first two measurements and those being
6
7 overweight at first and obese at second measurement were at increased risk.
8
9

10
11 Results for non-obesity-related cancers were displayed in Tables S6-S11. For
12
13 cancers of the larynx, lung and trachea, inverse associations were seen for several BMI and
14
15 weight metrics (Table S7), but these associations disappeared when the analysis was
16
17 restricted to those who never smoked. The latter analysis, however, was based on small
18
19 numbers.
20
21
22

23
24 Further adjustment for BMI at first measurement in the models generally had
25
26 little impact on the risk estimates. However, the associations of BMI at last measurement,
27
28 maximum BMI and OBY with male liver cancer and of BMI at last measurement with male
29
30 renal cell cancer were weakened. Cancer-specific adjustments in sensitivity analyses within
31
32 the cohorts also had minor impact on the estimates. When follow-up started one year after
33
34 the health examinations, no major changes in risk were seen for obesity-related cancers
35
36 overall.

Discussion

In this large population-based study, duration of overweight (males only) and obesity over time were associated with increased risk of all obesity-related cancers combined. Being overweight before age 40 increased the risk of these cancers by approximately 15%, with higher risks particularly for endometrial, male renal cell, and male colon cancer.

Study Strengths and Limitations

Major strengths of our study were its prospective design and large size, including approximately 9,800 obesity-related cancers. We used data from population-based health examinations in Austria, Norway, and Sweden, with almost complete coverage of measured exposure factors (height and weight).¹¹ We also used high-quality national cancer registries for follow-up.¹³⁻¹⁵

The risks of postmenopausal breast and endometrial cancer associated with overweight and obesity have previously been shown to be modified by postmenopausal hormone use.⁵ Although this effect modification has been similar between studies,^{20;21} others have found no effect modification of the BMI-breast cancer relationship by postmenopausal hormone use.²² Unfortunately, we had no information on postmenopausal hormone use in our data.

Although it has been suggested that other anthropometric measures than BMI (e.g. waist-to-hip ratio and waist circumference) better explain obesity-related health,²³ BMI is strongly correlated to percentage body fat within sex-age groups and may be useful for separating body fat categories at the population level.²⁴ It has also been argued that weight gain is a better metric than BMI change.⁴ In our study, different BMI and weight metrics were constructed to capture various aspects of adult weight gain over time. These metrics

1
2
3 are highly correlated, and consequently, it is difficult to separate their effects. Further,
4
5 information on waist circumference or waist-to-hip ratio was not available in all cohorts,
6
7
8 and was not used in our analyses.
9

10
11 BMI at first and last measurement show the results of the first and last surveys
12
13 for the individuals in our study, although they were performed at different ages and
14
15 calendar time. For the cancer patients, mean time between last measurement and diagnosis
16
17 was 10 years (range; 0-35 years), indicating that most had their last measurement taken
18
19 long time before diagnosis. We displayed results for five BMI trajectories, including 92% of
20
21 the study population. Moreover, 3.6% of the study population were overweight at first
22
23 measurement and had normal BMI at second, 0.1% were obese at first measurement and
24
25 had normal BMI at second, 0.4% had normal BMI at first measurement and obese at
26
27 second. However, we consider these and other groups of similar size to be too small to
28
29 make meaningful analyses.
30
31
32
33
34
35

36 The first BMI measurement above 25 indicated when an individual was
37
38 overweight for the first time. Further, the length of time as overweight (OWY) or obese
39
40 (OBY) were estimated based on known BMI-measurements, allowing us to take the degree
41
42 of overweight and obesity for each individual over time into account. This has been a better
43
44 approach for many obesity-related outcomes than cross-sectional BMI information.²⁵
45
46
47

48 Since we were unable to differentiate between intentional and unintentional
49
50 weight loss, the influence of comorbidities and reverse causation is a concern. However, no
51
52 major changes in risk estimates were seen when follow-up started one year after the health
53
54 examinations. Also the risk of the obesity-related cancers increased consistently with
55
56 increasing maximum BMI in our study. This metric appears to be unaffected by disease-
57
58
59
60

1
2
3 associated weight loss in studies on the mortality risk of obesity,²⁶ and has been used to
4
5 minimize confounding by disease when weight histories are unavailable.
6
7

8
9 One of the main aims of our study was to explore the impact of BMI and
10
11 weight changes over time on obesity-related cancers. Consequently, our study population
12
13 was restricted to those with two or more health examinations, and we only included
14
15 individuals with measurements at least three years apart. There were no major differences
16
17 between basic characteristics, such as BMI at first measurement, of those with
18
19 measurements from two or more surveys and those with only one measurement. Never-
20
21 smokers at first examination, however, were more likely to be included than smokers (55%
22
23 never-smokers among the study participants vs. 39% among those excluded).
24
25
26
27

28
29 We presented results for obesity-related cancers combined and for major
30
31 obesity-related cancers according to various BMI and weight measures, which may raise
32
33 concern about false positive associations. However, we only presented results for
34
35 associations between BMI and weight measures and known obesity-related cancers. For
36
37 comparison, however, we also showed results for non-obesity-related cancers.
38
39
40

41 ***Comparisons with Other Studies***

42
43

44 For postmenopausal breast cancer, adult weight gain has consistently been positively
45
46 associated with risk and strongest for estrogen and progesterone receptor positive tumors,
47
48 whereas excess weight has been inversely associated with risk of premenopausal breast
49
50 cancer.^{9;27-30} However, it has also been suggested that short-term weight gain could increase
51
52 the risk of breast cancer in premenopausal women.⁸ In our study, one unit increase in BMI
53
54 and 5 kg increase in weight as well as duration of obesity were associated with increased
55
56
57
58
59
60

1
2
3 risk of postmenopausal breast cancer. Being overweight before age 40 did not, however,
4
5 increase the risk.
6
7

8 Excess weight or greater BMI are key risk factors for endometrial cancer, and
9
10 more than 40% of all new cancers in Northern Europe are attributable to high BMI.^{31;32}
11
12 Epidemiological studies suggest that obesity is associated with both main histological
13
14 subtypes of endometrial cancer (type I and II), although to a lesser extent among type II.^{33;34}
15
16 Adult weight gain has also consistently been associated with endometrial cancer risk among
17
18 women not using postmenopausal hormone therapy.^{4;5} Although obesity throughout life
19
20 has been positively associated with risk, adult or current obesity seem to play the most
21
22 critical role.^{10;35} Other studies suggest that excess weight during adolescence and young
23
24 adulthood also contribute to risk.^{36;37} In our study, one unit increase in BMI and 5 kg
25
26 increase in weight, duration of overweight and obesity as well as overweight before age 40
27
28 were associated with increased risk.
29
30
31
32
33
34
35

36 Ovarian cancer is regarded as obesity-related,² and 6% of all new cancers in
37
38 Northern Europe are attributable to high BMI.³¹ Also adult weight gain has been associated
39
40 with increased ovarian cancer risk.⁴ We have previously reported on an increased ovarian
41
42 cancer risk in women who were overweight or obese in adolescence or young adulthood.³⁸
43
44 In the present study, however, no associations were seen for the BMI and weight metrics,
45
46 which may be due to the relatively high mean age at first health examination (approximately
47
48 42 years).
49
50
51
52

53 For colon cancer, a stronger and more consistent association with obesity has
54
55 been reported in males than females.^{29;39} A 2015 meta-analysis of adult weight gain and
56
57 adiposity-related cancers showed that 5 kg increase in weight increased the risk of male, but
58
59
60

1
2
3 not female colon cancer.⁴ A US cohort study of postmenopausal women, however, found
4
5 that longer duration of overweight and obesity were associated with colon cancer.⁵ It has
6
7
8 also been reported that weight gain from early adulthood to midlife is associated with
9
10 higher colorectal cancer risk than weight gain from midlife to older ages.⁴⁰ Duration of
11
12
13 overweight (females) and obesity (males and females) were associated with risk of colon
14
15
16 cancer in our study, as well as overweight before age 40 (males).

17
18 For renal cell cancer, a positive dose-response relationship between BMI and
19
20 risk has been reported in both genders.⁴¹ In a 2015 meta-analysis of prospective
21
22
23 observational studies, those with greater adult weight gain were associated with an
24
25
26 increased risk of kidney cancer.⁴ A longer overweight duration increased the risk of female
27
28 kidney cancer in a longitudinal US study.⁵ In our study, duration of overweight (males) and
29
30
31 obesity (males and females) as well as overweight before age 40 (males) were associated
32
33
34 with increased risk.

35
36 The velocity of weight gain and duration of overweight and obesity at different
37
38 points during one's life course probably influence cancer risk to different degrees.²⁹ Excess
39
40
41 weight in adolescence and young adulthood increases the risk of cancers linked to adult
42
43
44 overweight and obesity.^{38;42} Those being overweight before age 40 had an increased risk of
45
46
47 all obesity-related cancer by 16% and 15% in males and females, respectively, in our study,
48
49
50 specifically for endometrial (70%), male renal cell (58%), and male colon cancer (29%).

51
52 Obesity has a multifactorial etiology involving a complex interplay between
53
54
55 lifestyle, environment, nutrition, genetics and epigenetic predisposition. The underlying
56
57
58 biological mechanisms for the association between adiposity/weight gain and cancer may
59
60

1
2
3 involve changes in sex hormone metabolism, insulin and IGF (insulin-like growth factor)
4
5 signalling, and adipokine pathophysiology/inflammatory pathways.⁴³
6
7

8
9 In summary, this study showed that adult weight gain was associated with
10
11 increased risk of several major cancers. The degree, timing and duration of overweight and
12
13 obesity also seemed to be important. Overweight and obesity are important modifiable risk
14
15 factors for several cancers, and preventing weight gain may be an important public health
16
17 strategy to reduce the cancer risk.

Funding

No specific funding was received for this study.

Acknowledgements

We thank all participants of the cohorts. In Norway, we thank the screening team of the former National Health Screening Service of Norway, now the Norwegian Institute of Public Health. We also thank all scientists and organizations behind the VIP cohort and Åsa Ågren and her team at the Department of biobank research for coordinating the VIP data. In the MPP, we thank Anders Dahlin, database manager of the cohort. In the VHM&PP, we thank Elmar Stimpfl and Karin Parschalk for excellent technical support as well as Markus Wallner, Christian Bernhard, and Gabriela Dür from the Vorarlberg State Government.

Conflict of interest

None declared.
